JMultiEquals

The template class JMultiEquals resides in the name space JLANG and constitutes an auxiliary base class. Like the template class JEquals, it implements the (not-)equal operators == and != of a derived class. In this case, the class can be derived from multiple other base classes, some of which providing for the policy method equals. Here, a second template argument is used that corresponds to a so-called type list. The (not-)equal operators of the derived class corresponds to the (not-)equal operators of the base classes in the type list. The type list can conveniently be specified with class JTYPELIST.

For example, the following classes A and B derive from JEquals.

```
struct A :
                                                   struct B :
   public JEquals<A>
                                                     public JEquals<B>
 {
                                                   {
   A(int value) :
                                                     B(int value) :
     value(value)
                                                       value(value)
   {}
                                                     {}
   bool equals(const A& object) const
                                                     bool equals(const B& object) const
   {
                                                     {
    return this->value == object.value;
                                                       return this->value == object.value;
   }
                                                     }
   int value;
                                                     int value;
 };
                                                   };
```

Here, the classes C and D derive from MultiJEquals but with different type lists.

```
struct C :
                                                   struct D :
  public A,
                                                     public A,
  public B,
                                                     public B,
  public JMultiEquals<C, A>
                                                    public JMultiEquals<D, JTYPELIST<A, B>::typelist>
ł
                                                   {
  C(const int a,
                                                    D(const int a,
    const int b) :
                                                       const int b) :
    A(a),
                                                       A(a),
    B(b)
                                                       B(b)
  {}
                                                     {}
};
                                                  };
```

The following example

```
C c1(1,1);
C c2(0,1);
C c3(1,0);
cout << (c1 == c1) << endl;
cout << (c1 == c2) << endl;
cout << (c1 == c3) << endl;
```

will produce

1 0

and

```
D d1(1,1);
D d2(0,1);
D d3(1,0);
cout << (d1 == d1) << endl;
cout << (d1 == d2) << endl;
cout << (d1 == d3) << endl;</pre>
```

will produce

1 0 0

Note that without JMultiEquals, the compiler would have detected an error due to the ambiguity of the the (not-)equal operators.
